Do the odds match outcomes?

A shareable summary of the current dashboard. Open the linked live dashboard for every filter, source archive and downloadable dataset.

At one day before the archive cutoff: 277,375 eligible contracts across six venues. Favorites won 81.27% of the time; their prices implied 81.29%. The Brier score was 0.125.

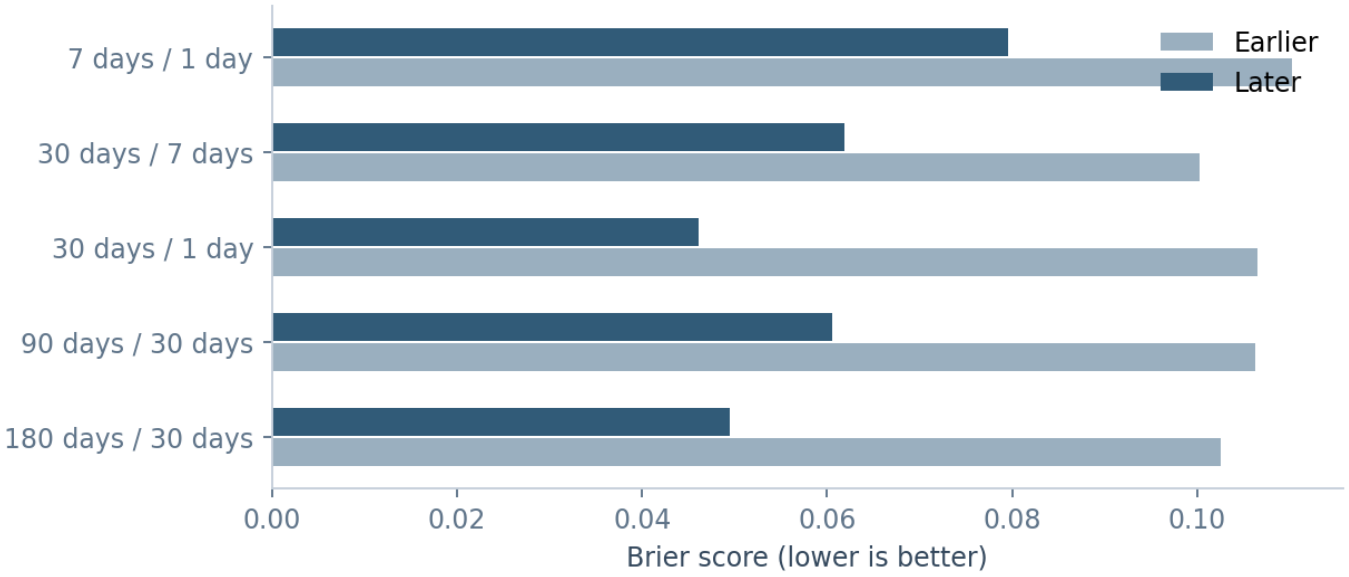

Read this carefully. An overall gap near zero can hide errors within categories or probabilities. High win rates alone do not prove good forecasting. Each plotted point uses an exact whole-percent quote, not a ten-point band.

The combined view includes five real-money venues plus Manifold play-money markets. Contracts on different venues can describe the same underlying event. Archive cutoffs are not always the time the outcome became known.

Coverage: Polymarket, Kalshi, PredictIt, Iowa Electronic Markets, Intrade and Manifold. The full dashboard includes politics, sports, weather, finance, crypto, culture, technology and other categories.

Do forecasts improve closer in?

Compare the same contracts at both horizons; otherwise the mix of events can make one day appear worse than seven days.

The matched samples improve at every comparison shown. For seven versus one day, the same 42,697 contracts improve from 0.1102 to 0.0795 Brier. This describes the selected contracts, not a causal effect of waiting.

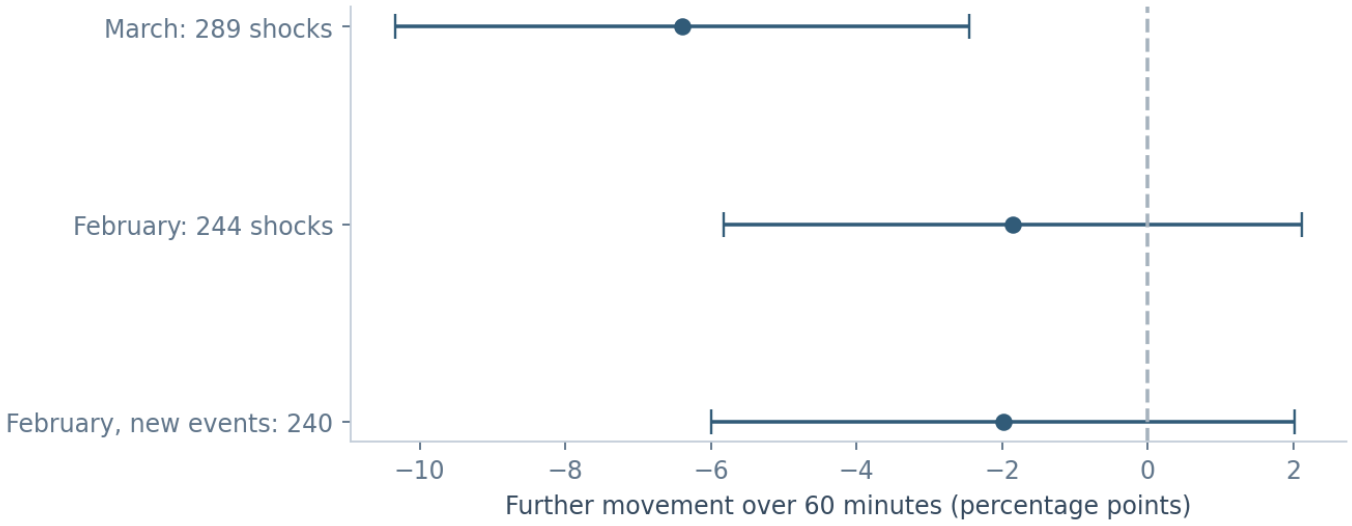

Why the raw horizon chart can look different: one-day contracts include many short-lived markets absent at longer horizons. Matching removes that change in composition, but still selects contracts with observations at both dates.

Remaining limits: the favored side can change between dates. Qualification requires a favorite of at least 51% on both dates. A reported close or expiry may follow the moment the result became public.

The dashboard also compares categories, calendar periods, volume groups, exact quoted probabilities, quote age, event weighting and bid-ask spreads.

Do sharp jumps overreact?

Observed reversals are descriptive evidence. They do not alone establish behavioral overreaction to one identified news item.

Large-jump result: rises of at least 20 points subsequently reversed 6.4 points on average in March. Frozen rules applied to February gave about 2 points of reversal; its uncertainty includes no average reversal.

March's result survives equal-event weighting, calendar-day resampling and the stated repeated-testing correction. It is not clearly established outside sports. February does not prove the months differ; its interval still permits a meaningful reversal.

Missing observations matter. Only 289 of 877 selected March shocks have complete paths. Extreme allowable values for missing one-hour prices give a logical mean-drift range of -33.14 to +5.65 points among still-open contracts. That is a bound, not a confidence interval.

Other checks compare quiet periods and Kalshi trade prices with bid-ask midpoints. Matching support is limited, and the Kalshi quote sample cannot directly validate the Polymarket result.

How quickly is news reflected?

The current independently timed benchmark covers three official March 2026 releases: jobs, inflation and the Fed decision.

At the first five-minute observation: 29 of 31 contracts have prices. Of those 29, 27 are within five percentage points of final payout; two losing contracts still trade at 45% and 11%. Missing contracts cannot be classified.

That does not establish a general five-minute reaction time. Only 16 contracts have both before/after five-minute prices, four have complete 15-minute paths, and none have complete 60-minute paths. Some outcomes, particularly the Fed decision, were already priced before release.

Five-minute bars cannot distinguish a reaction in seconds from one taking minutes. These announcements directly determine the contract answer. News that merely changes an unresolved probability requires a different benchmark.

How the analysis protects against overclaiming

- Earlier-period replication with fixed rules and separate event groups.
- Related contracts grouped when estimating uncertainty.
- Same observations used for paired comparisons.
- Missing prices kept missing; no interpolation or zero-change substitution.
- Official release clocks separated from price-implied news times.
- Explicit source coverage, settlement rules, costs and timing caveats.

Current conclusion: the observed March sample shows large-jump reversals, but systematic overreaction across markets remains unproven. The small official-release benchmark illustrates rapid adjustment with exceptions, not a universal processing speed.
